## OBJECTIVE

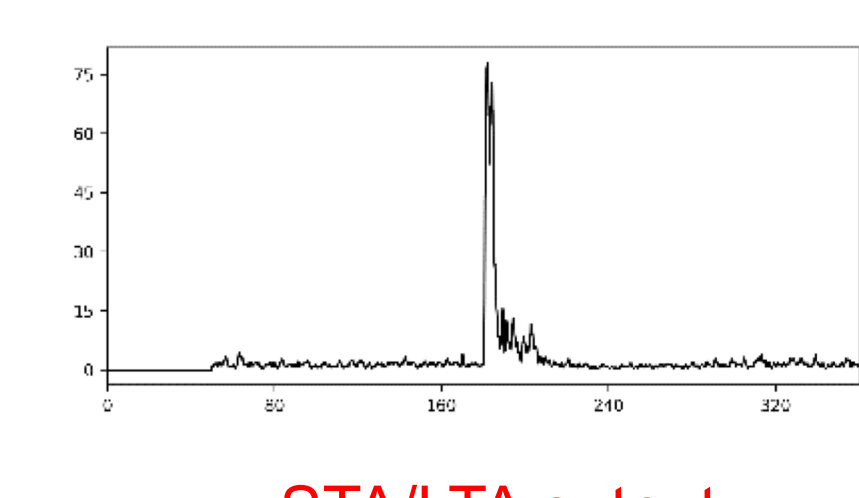

Develop a method to fuse outputs of diverse seismic wave arrival detectors (algorithms) to improve performance i.e., reduce false positive and negative rates

- Use hidden Markov models (HMM)s to implement the fusion scheme
- Test on P-wave arrivals recorded at WB2, Warramunga IMS stations, NT, Australia

## BACKGROUND

- A raw seismogram may show an abrupt commencement of activity (depending on SNR), indicating the arrival of a seismic wave
 

Waveform
- An analyst picks a time as the time of arrival of the seismic wave
 

Analyst's pick
- Detector algorithms like STA/LTA compute a function, derived from the seismic waveform, that has a "spike"
 

STA/LTA output
- The timing of the "spike" should be close to the arrival time
- The seismic waveform may have to be bandpass filtered first to enhance the signal relative to background noise
- Multiple detection algorithms add robustness: It is unlikely that a non-seismic (confounding process) will cause all detector algorithms to misfire at the same time
- Thus a simultaneous "spike" (a large change in detector function value) across multiple detector algorithm should indicate a seismic wave arrival with high confidence
- It should also reduce false positive (FP) and false negative (FN) rates
- But how to harness the joint predictive power of multiple detector algorithms?
- Premise:** The fusion could be performed using hidden Markov models (HMMs)

## FORMULATION

### The Hidden Markov Model (HMM)

- Consider a system that occupies one of  $N$  states at time  $t$ , and moves to a new state at time  $t+1$
- $H_t = \{h_i\}$ ,  $i = 1 \dots N$ , are the probabilities that the system is in state  $i$  at time  $t$
- Consider, too, that the system evolves as  $H_{t+1} = [P] H_t$ 
  - Here  $[P]$  is a  $N \times N$  matrix
  - $p_{ij}$  is the probability of transitioning from state 'i' to state 'j' in one timestep, and is constant over time
  - This is a **Markov** system
- The state of the system is not seen (i.e., **hidden**), but it causes observable phenomenon
- Let the observed state of the system at time  $t$  be one of  $K$  states
  - Let  $O_t = \{o_k\}$ ,  $k = 1 \dots K$  be the probabilities that the system is in observed state 'k'
  - Also  $O_t = [M] H_t$ ,  $[M]$  is a  $K \times N$  matrix
  - $m_{ki}$  is the probability of hidden state  $i$  causing observed state  $k$
- Such a discrete-time, discrete-state model for a time-dependent system is called a hidden Markov model (HMM)

### Learning HMMs

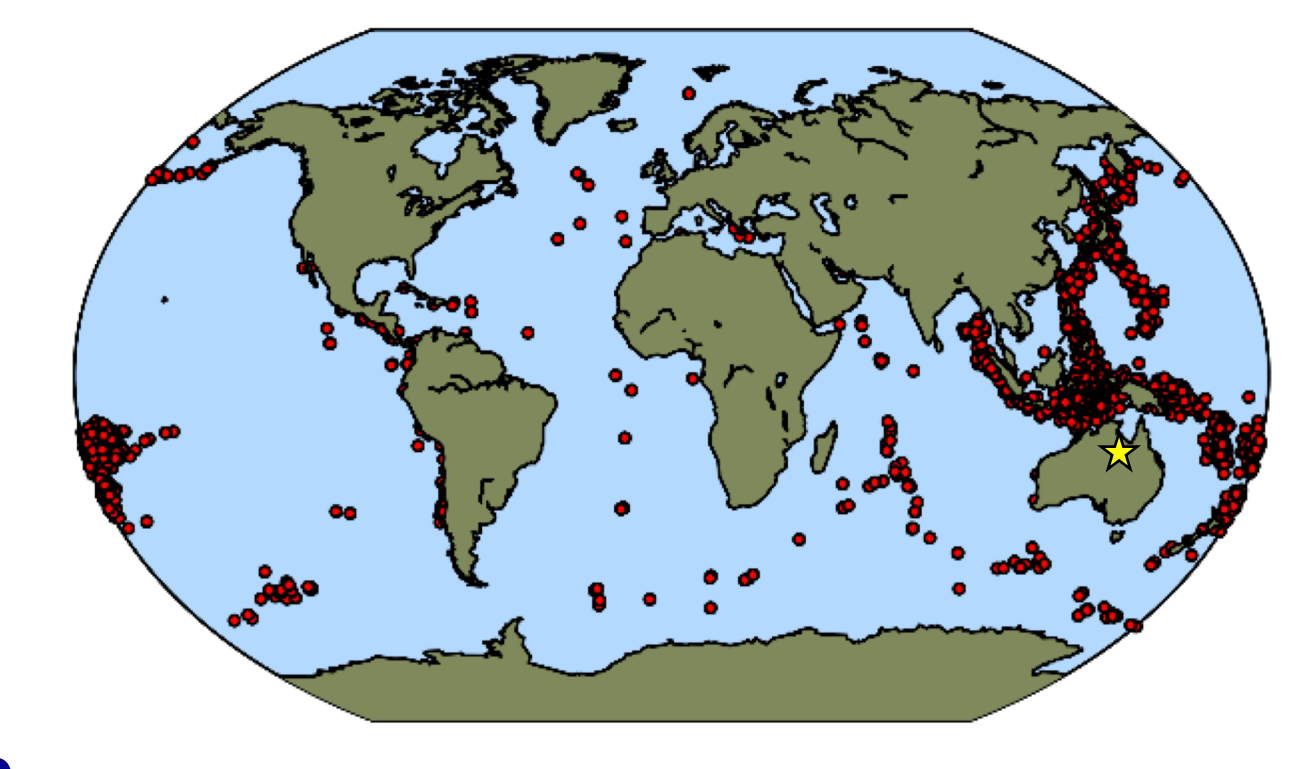

- Given a long sequence of true internal states, one can learn the **transition** matrix  $[P]$
- Given a long sequence of observed states, one can learn the emission matrix  $[M]$  from  $H_t$
- If only observed states are available, along with guesses  $[P^*]$  and  $[M^*]$ , one can:
  - Adjust  $[P^*]$  to get  $[P]$  and  $[M^*]$  to get  $[M]$ ; also infer internal states  $H_t$

### Fusion model

- The seismogram is supposed to be a binary system, capable of being in  $S = \{s_1, s_2\}$ ,  $s_1 =$  noise or  $s_2 =$  seismic signal
- We have defined 10 observables. Each observable has many measured values which is represented as a Gaussian
- 3 observables are outputs of seismic wave detection algorithms. They should have a spike at the arrival time
- The other 7 observables also assume very different values for noise versus P-waves, e.g. rectilinearity. They help recognize the seismic signal.

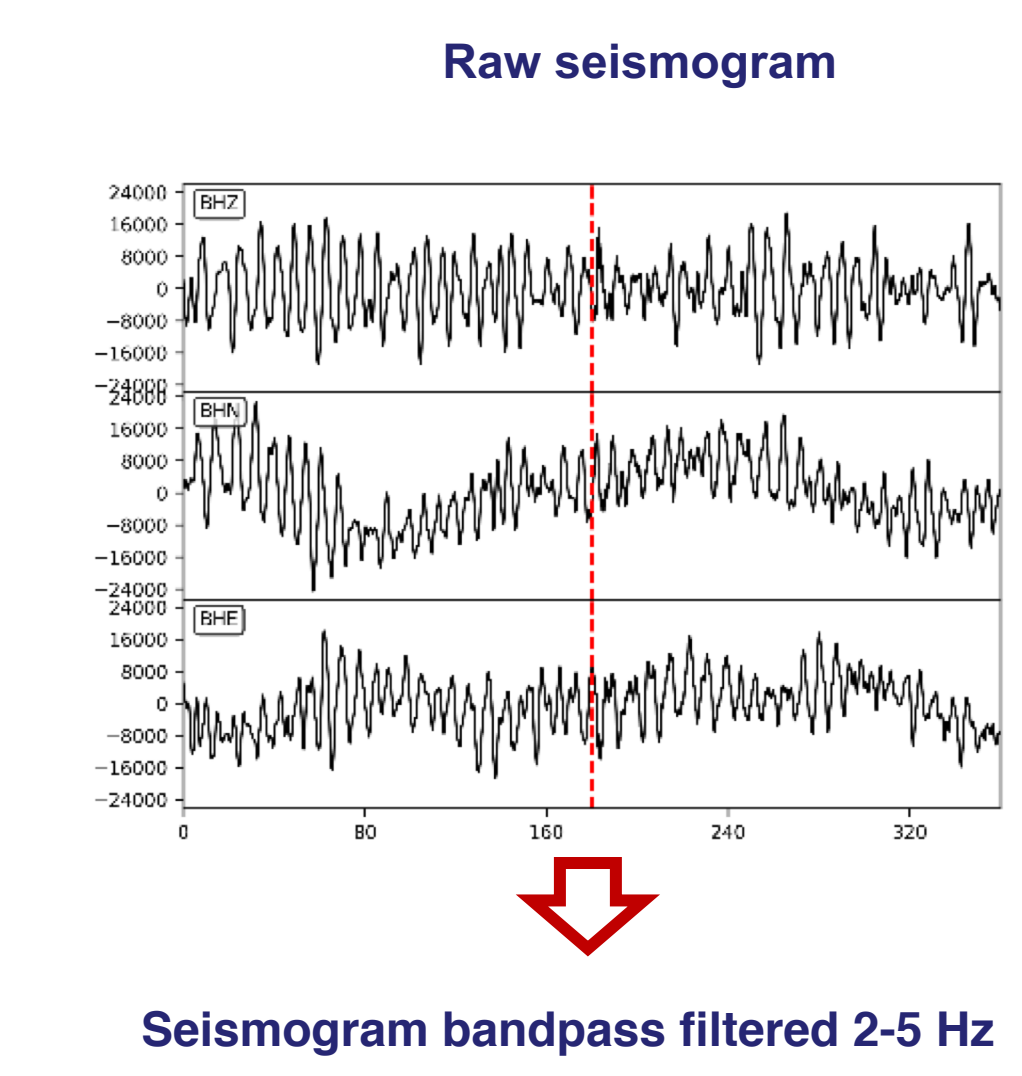

## FEATURIZING THE DATA

### Data

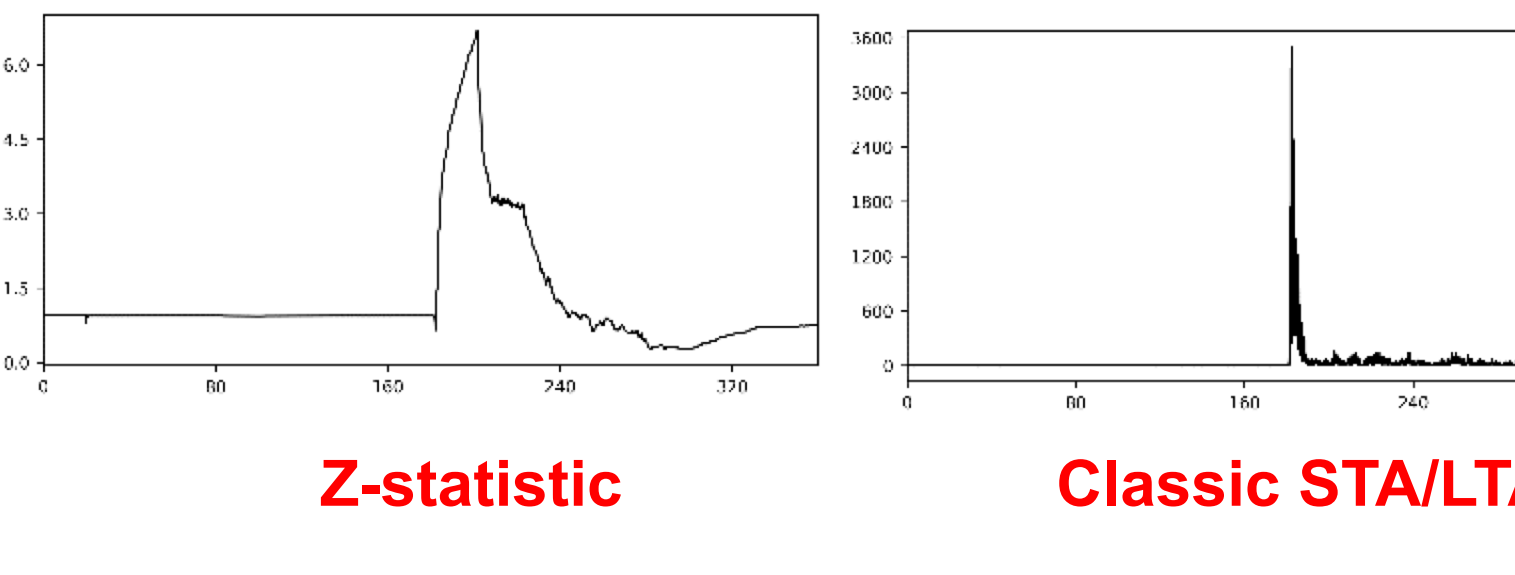

- The dataset contains 835 P-wave arrivals as measured by the 3C station WB2 at Warramunga, NT, Australia
 

Map of WRA station (yellow star) and seismic events (red circles)
- The sources of these arrivals are events at regional and teleseismic distances from WB2; an analyst picked the arrivals manually

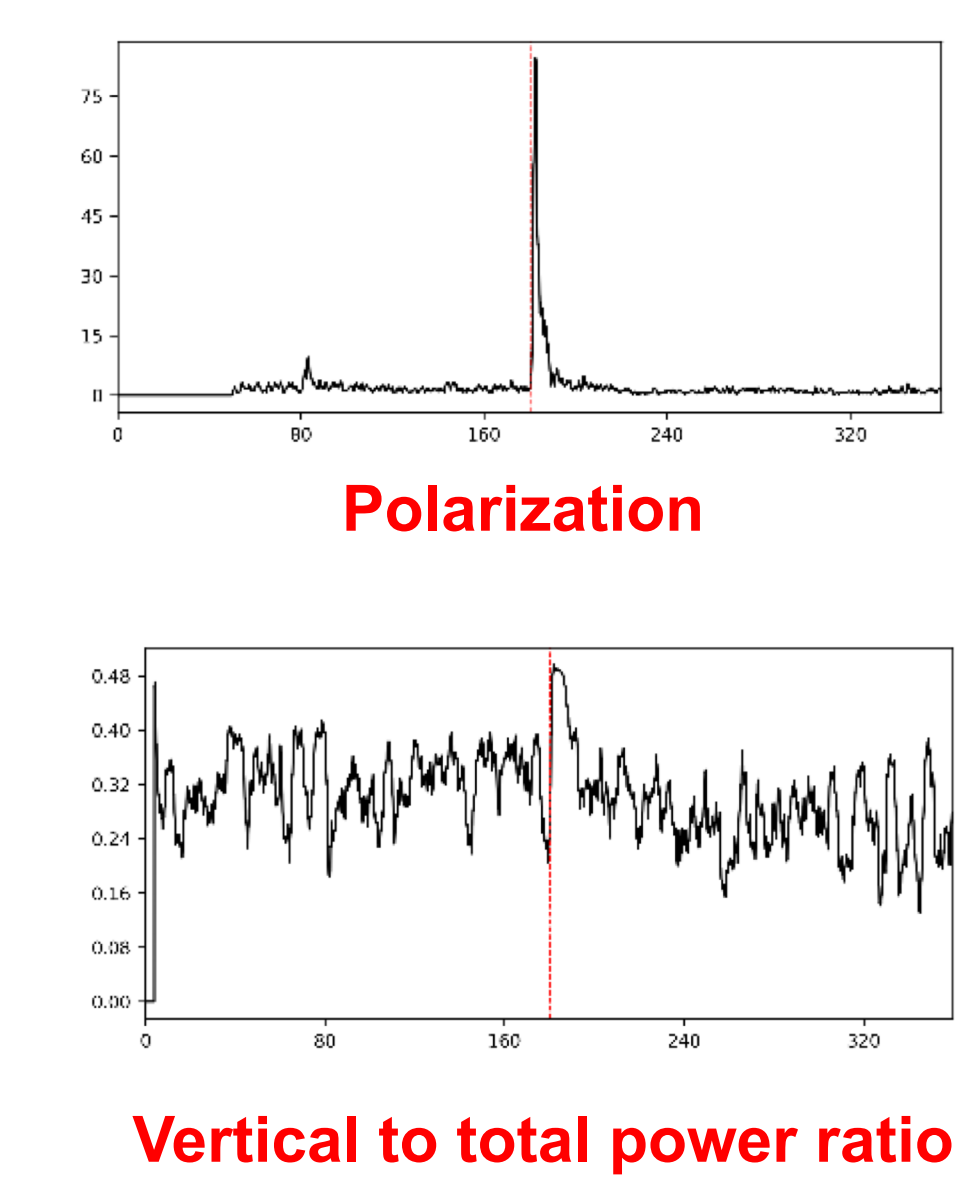

### Features

- The waveform was bandpass-filtered in (1.5, 3), (3, 6), (2, 5) & (6, 12) Hz bands
 

Raw seismogram

Seismogram bandpass filtered 2-5 Hz
- In each band, the classic STA/LTA, recursive STA/LTA and Z-statistic algorithms provided the 3 observables with spikes to denote arrivals
 

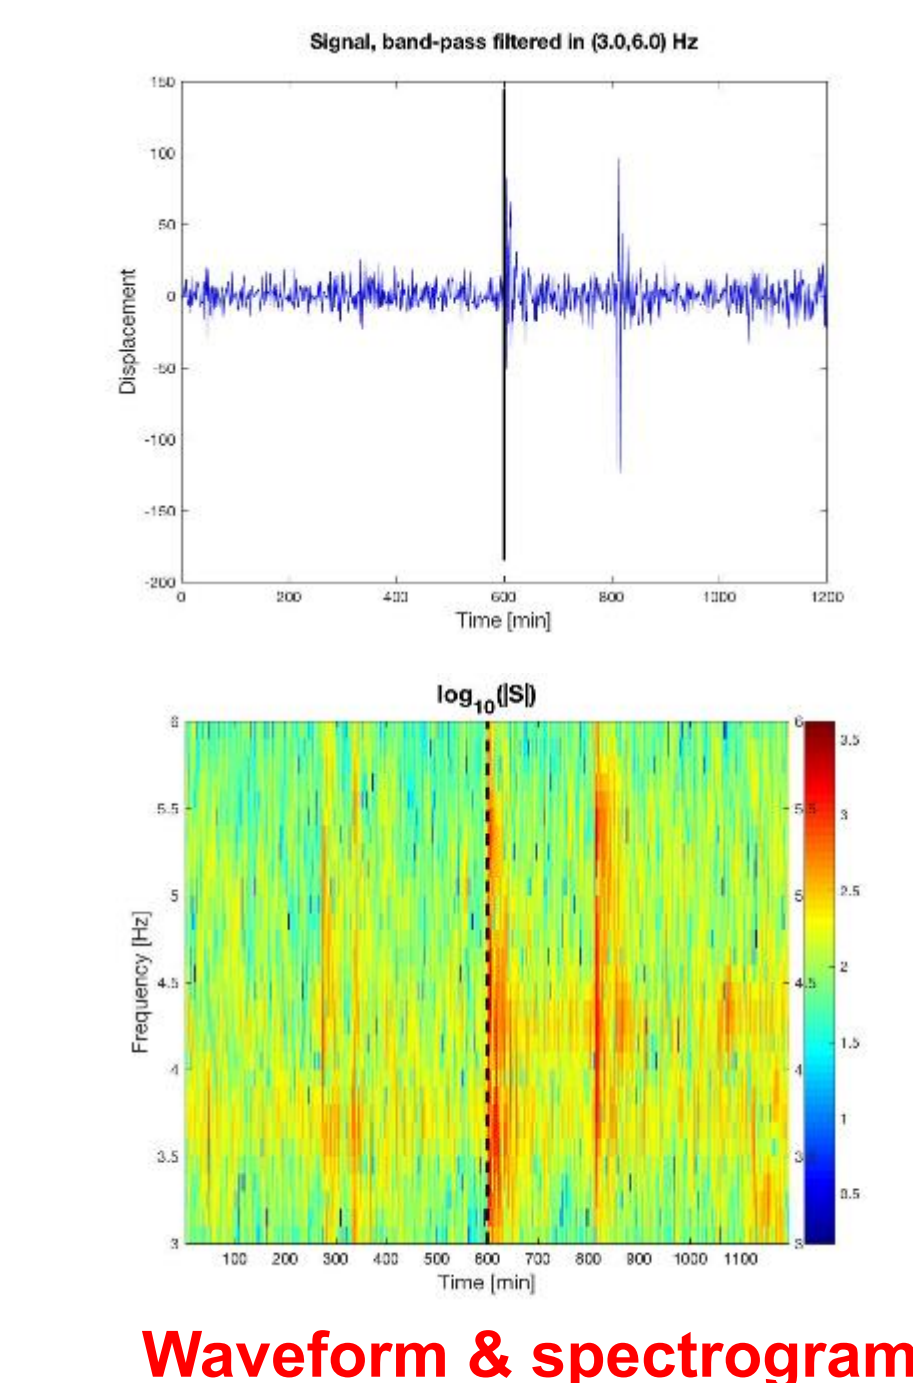

Z-statistic

Classic STA/LTA
- In each band we computed polarization, rectilinearity, planarity, azimuth, angle of incidence and ratio of vertical to total power
 

Polarization

Vertical to total power ratio
- We also compute the area, in different frequency bands, under the PSD curve computed from the sonogram

### Constructing and testing HMMs

- The internal state of the HMM was computed by setting the state to 1 over a 4-second duration starting from the pick time.
- The HMM was trained over 80% of the dataset and tested over the remaining 20%
- The observed data of the test set was used to infer the internal (hidden) state (0-1 rise)
- Predicted arrival times were compared with the analyst time for the test waveforms
 

Waveform & spectrogram

## RESULTS

- Two Gaussian HMMs were trained using 10-fold cross-validation
- One HMM was trained using the 3 detector algorithms' outputs as the observables
- The second also had the other observables (rectilinearity, etc.)
- If the HMM's predicted arrival time was within a few seconds of the analyst's, it was deemed a true detection

Detections		HMM (Detection algorithms only)		Classic STA/LTA		Z-Statistic	
		True	Missed	True	Missed	True	Missed
Expert-picked	True	774	61	753	82	219	616
	False	457		2879		1187	

- The performance of the HMM-based fused detector is summarized using the precision & recall
- TD: True Detection; FD: False Detection; FM: False Misses

$$\text{Precision} = \frac{TD}{TD+FD}$$

$$\text{Recall} = \frac{TD}{TD+FM}$$

	HMM (Detection algorithm only)	Classic STA/LTA	Z-Statistic
Precision	0.63	0.21	0.16
Recall	0.92	0.90	0.26

## CONCLUSIONS

- The fusion of the 3 detector algorithms improved precision and recall compared to the individual algorithms
- Polarization etc., when used as features improved recall slightly, at the expense of recall
- However precision is still very low, and there are lots of FP.
- Future work:** Train two HMMs, one each for noise and P-waves, and model-select between the two for a signal
